ABSTRACT

At the onset of high-mass star formation, accreting protostars are deeply embedded in massive cores made of gas and dust. Their spectral energy distribution is still dominated by the cold dust and rises steeply from near- to far-infrared wavelengths. The young massive star-forming region IRDC 18223-3 is a prototypical infrared dark cloud with a compact millimeter continuum core that shows no protostellar emission below 8 μm. However, based on outflow tracers, early star formation activity was previously inferred for this region. Here we present recent Spitzer observations from the MIPS-GAL survey that identify the central protostellar object for the first time at 24 and 70 μm. Combining the mid- to far-infrared data with previous millimeter continuum observations and the upper limits below 8 μm, one can infer the physical properties of the central source. At least two components with constant gas mass M and dust temperature T are necessary: one cold component (∼15 K and ~576 M⊙) that contains most of the mass and luminosity, and one warmer component (≥51 K and ≥0.01 M⊙) to explain the 24 μm data. The integrated luminosity of ~177 L⊙ can be used to constrain additional parameters of the embedded protostar from the turbulent core accretion model for massive star formation. The data of IRDC 18223-3 are consistent with a massive gas core harboring a low-mass protostellar seed of still less than half a solar mass with high accretion rates of the order 10−3 M⊙ yr−1. In the framework of this model, the embedded protostar is destined to become a massive star at the end of its formation processes.

1. INTRODUCTION

The onset of massive star formation was elusive to observational research until recently. Very young regions of massive star formation contain large amounts of cold gas and dust observable from far-infrared (FIR) to millimeter wavelengths. A possibly luminous, embedded object has not yet formed or is obscured by the large optical depth of the surrounding cold dust at near-/mid-infrared wavelengths (NIR/MIR). The advent of the Infrared Space Observatory and the Midcourse Space Experiment allowed us to identify large numbers of such infrared dark clouds (IRDCs; Egan et al. 1998; Bacmann et al. 2000; Carey et al. 2000; Simon et al. 2006). However, the IRDCs are not a well-defined class, but these clouds are expected to harbor various evolutionary stages. Adopting the evolutionary sequence outlined in Beuther et al. (2007), IRDCs should be capable of containing genuine high-mass starless cores (HMSCs), high-mass cores harboring accreting low-/intermediate-mass protostars, and the youngest high-mass protostellar objects. While the first group is important for studying the physical conditions of massive cores before the onset of star formation, the latter two stages are essential for understanding the early evolution in massive star formation. Since the evolutionary timescale for the formation of high-mass stars is short (of the order 107 yr, e.g., McKee & Tan 2002), and since the central evolving protostars are deeply embedded within their natal cores, observational discrimination between these different evolutionary stages of IRDCs is a challenging task.

Recently, Beuther et al. (2005) observed with the Plateau de Bure Interferometer (PdBI) a filamentary IRDC containing a compact 3.2 mm continuum peak related to a massive core that remains undetected up to 8 μm in the Spitzer Galactic Legacy Infrared Mid-Plane Survey Extraordinaire (GLIMPSE; Fig. 1, left panel). Based on the GLIMPSE nondetection, one could speculate that this may be a genuine HMSC; however, there are additional indicators leading in the opposite direction. The Spitzer 4.5 μm band shows weak emission right at the edge of the 3.2 mm continuum core. This so-called green-fuzzy emission is usually attributed to shock-excited H2 emission, which is especially prominent in this band (Noriega-Crespo et al. 2004). Such H2 features can be attributed to early outflow activity. This scenario is supported by single-dish CO and CS spectra showing non-Gaussian line-wing emission indicative of molecular outflows. Furthermore, NH3 (1, 1) and (2, 2) inversion line observations revealed relatively high gas temperatures of the order 33 K that would not be expected in the case of a starless core. Therefore, Beuther et al. (2005) argue that we are witnessing the onset of massive star formation. Based on the outflow signatures and the high NH3 temperatures, a central protostar should have formed already, but it must still be in a very early evolutionary stage to remain undetected up to 8 μm. The detection of at least three 4.5 μm outflow features indicates that even a multiple system may be embedded in this core. At a temperature of 33 K and a distance of ~3.7 kpc (Sridharan et al. 2002, 2005), Beuther et al. (2005) calculated from the 3.2 mm continuum flux a mass and column density of the gas core of ~184 M⊙ and ~10^24 cm^-2, respectively (A_v ~ 1000).

In the framework of the above-mentioned evolutionary sequence, IRDC 18223-3 should be part of the high-mass cores harboring accreting low-/intermediate-mass protostars. For such a source, it is expected that the spectral energy distribution (SED) rises sharply at mid- to far-infrared wavelengths and should hence become detectable there. The newly released Spitzer Legacy survey MIPS-GAL (MIPS Inner Galactic Plane Survey) is the ideal resource to search for such MIR/FIR emission and to study this young source in more detail.

2. DATA

The MIPS (Multiband Imaging Photometer for Spitzer) 24 and 70 µm data were taken from the Spitzer archive of the recently released MIPSGAL survey (Carey et al. 2005). Fluxes were extracted via aperture photometry subtracting the background emission from a close-by region. The Spitzer IRAC (Infrared Array Camera) 3.5–8 µm and the PdBI 3.2 mm continuum data were first presented in Beuther et al. (2005). Furthermore, we use a 1.2 mm continuum flux measurement observed with the IRAM 30 m telescope (Beuther et al. 2002). For the 3.2 mm data, we use the flux within the 50% contour level (radius of ~10,000 AU) to avoid contamination from the large-scale filament. Similarly, for the 1.2 mm data, we use the peak flux measurement within the central 11" beam. Beuther et al. (2005) estimated for the whole large-scale filamentary structure that the PdBI observations suffer from about 25% of missing flux. However, since here we are not interested in the whole filament but only analyze the flux from the central compact peak emission, this effect is considerably lower. The accuracy of the flux measurements at millimeter wavelengths is estimated from the data to be correct within ~15% and for the 24 and 70 µm within 20%. The 3 σ upper limits of the four Spitzer IRAC data sets are 0.05 mJy at 3.6 and 4.5 µm, 0.13 mJy at 5.8 µm, and 0.15 mJy at 8 µm (Beuther et al. 2005).

3. RESULTS

Figure 1 presents overlays of the MIPS/IRAC mid-/far-infrared data and the 3.2 mm observations. The most striking result is that the 3.2 mm core, which is dark at least up to 8 µm, is now detected in the 24 and 70 µm bands. Previously, we could only indirectly infer from outflow indicators and warm gas temperatures that the core likely harbors already a very young protostar, but the new 24 and 70 µm data clearly identify this source now for the first time shortward of 100 µm.

Combining the 3.2 and 1.2 mm data from the Rayleigh-Jeans part of the spectrum with the 24 and 70 µm fluxes on the Wien side of the SED, this data set allows us to derive the physical properties of this high-mass core at the onset of massive star formation in more detail. Table 1 presents the fluxes from 24 µm to 3.2 mm, and Figure 2 shows the resulting SED.

The spectral energy distribution was fitted with Planck blackbody functions accounting for the wavelength-dependent emissivity of the dust. The assumed dust composition follows Draine & Lee (1984). As a first-order approach, we tried to fit the data set with a single-component blackbody function. While this may work for the measurements upward of 70 µm, the 24 µm point shows significant excess emission to a single-component fit, and a second warmer component has to be added. Figure 2 presents a two-component fit to the data. While most of the flux, mass, and luminosity stem from the cold gas and dust with an approximate temperature of 15 K, we find another warm component with a temperature ≥51 K. The gas masses associated with the cold and warm components are ~576 and ≥0.01 M⊙, respectively. Since on the Wien side of the SED the emission is not
optically thin anymore, we consider the masses and temperatures of the warm component as lower limits. The mass difference of the cold component between the new fit and the older mass estimates from Beuther et al. (2005) is due to the lower dust temperature we now derive (15 K vs. 33 K from the NH\textsubscript{3} gas observations) and the different assumptions about the dust grain size distributions (following now Draine & Lee 1984, whereas previously we used the approach by Hildebrand 1983). Furthermore, the integrated luminosity one derives from this two-component fit is \( \sim 177 L_{\odot} \) (174 and 3 \( L_{\odot} \) in the cold and warm components, respectively).

4. DISCUSSION

Although we cannot fit the 24 \( \mu \text{m} \) flux measurements without the additional warmer component, it is clear that this component does not contribute significantly to the mass and luminosity of the region. In the regime of low-mass star formation, recently there have been several detections of very low luminosity objects (VeLLOs) within previously believed starless cores (Young et al. 2004; Dunham et al. 2006; Bourke et al. 2006). Some of these objects show clear outflow signatures (L1014, Bourke et al. 2005; IRAM 04191+1522, Dunham et al. 2006), and they are believed to be very young low-mass protostars or brown dwarfs likely associated with accretion disks. In the case of IRDC 18223-3, the region exhibits outflow signatures as well (Beuther et al. 2005); hence, it is likely that the warm component in this source is produced by an accreting low-mass protostar-disk system as well. An important difference between the VeLLOs and IRDC 18223-3 is that the luminosity of the warm component in IRDC 18223-3 is the same as that of the low-mass protostar object, whereas the estimated luminosity of IRDC 18223-3 includes likely multiple objects as well as potential contributions from external heating. Since massive star formation is usually proceeding in a clustered mode, multiple embedded protostars below our current angular resolution limit (5.8′′ × 2.4′′ at 3 mm wavelength corresponding to approximately 15,000 AU; Beuther et al. 2005) cannot be excluded. Nevertheless, it is likely that the luminosity of the region will be dominated by the most massive protostellar object, which is also confirmed by the simulations of Krumholz et al. (2007). Therefore, it appears reasonable to compare these simulations with our observational results.

The luminosity obtained for IRDC 18223-3 is reached in the simulations by Krumholz et al. (2007) already at extremely early times when the protostellar mass is still below half a solar mass. The corresponding accretion rates are of the order \( 10^{-4} M_{\odot} \text{yr}^{-1} \). Therefore, combining the model predictions with the observed properties of this region indicates that we are dealing with a massive gas core that harbors an embedded, accreting low-mass protostar with accretion rates that are high enough that it will eventually form a massive star.

Although the data do not allow us to unambiguously exclude that the embedded low-mass protostar may remain a low-mass object, potentially never forming a massive star, the fact that the gas core is very massive and that the luminosity is already relatively high (a genuine low-mass protostar has orders of magnitude lower accretion rates and hence a significantly lower accretion luminosity) strongly supports the proposed scenario of a massive star-forming region right at the onset of protostellar evolution and accretion.

The example of IRDC 18223-3 shows the power of combining (sub)millimeter high spatial resolution observations with the recently available NIR/MIR/FIR surveys of the Galactic plane by Spitzer. Combining these data sets allows us to con-
strain the SEDs of the youngest massive star-forming regions in unprecedented detail. This way we can observationally characterize the various evolutionary stages right at the beginning of massive star formation, in particular, the largely unknown properties of genuine high-mass starless cores and high-mass cores harboring low- to intermediate-mass protostars like the case of IRDC 18223-3. We are currently performing radiative transfer modeling that incorporates age estimates based on the emerging MIR flux, but this is not within the scope of the current Letter. For the coming years, we can expect studies of larger IRDC samples setting constraints on the source properties in a statistical sense.
